

Early Journal Content on JSTOR, Free to Anyone in the World

This article is one of nearly 500,000 scholarly works digitized and made freely available to everyone in the world by JSTOR.

Known as the Early Journal Content, this set of works include research articles, news, letters, and other writings published in more than 200 of the oldest leading academic journals. The works date from the mid-seventeenth to the early twentieth centuries.

We encourage people to read and share the Early Journal Content openly and to tell others that this resource exists. People may post this content online or redistribute in any way for non-commercial purposes.

Read more about Early Journal Content at <http://about.jstor.org/participate-jstor/individuals/early-journal-content>.

JSTOR is a digital library of academic journals, books, and primary source objects. JSTOR helps people discover, use, and build upon a wide range of content through a powerful research and teaching platform, and preserves this content for future generations. JSTOR is part of ITHAKA, a not-for-profit organization that also includes Ithaka S+R and Portico. For more information about JSTOR, please contact support@jstor.org.

THE SIGNIFICANCE OF SCUTE AND PLATE "ABNORMALITIES"¹ IN CHELONIA.

A CONTRIBUTION TO THE EVOLUTIONARY HISTORY OF THE CHELONIAN CARAPACE AND PLASTRON.

I. INTRODUCTION.

1. *Statement of the Problem.*

During a residence of several years on Lake Maxinkuckee, Marshall County, Indiana, my attention was repeatedly attracted to the large numbers and variety of species of tortoises that are found in the lake and in its accessory streams, swamps and pools.

In the spring of 1903 I began a study of the habits, variations,

¹ The word "abnormalities" in the title is used for lack of a better one, and includes supernumerary scutes and plates, deficiencies in these structures and cases of fusion. The word "diversities" might have been used with equal appropriateness.

etc., of these species, involving the collection of large numbers of individuals of all sizes. One of the most striking phenomena that came to light was the prevalence of many kinds of scute abnormalities, consisting for the most part of supernumary scutes on the carapace and plastron. As examples multiplied I became aware of a marked degree of regularity in these abnormalities, the same supernumerary scutes occurring in exactly the same locations time after time.

Diversity in scutes had been noted by two observers. Gadow ('99) studied *Thalassochelys caretta* (L.), a species with no fixed number or arrangement of scutes, and Parker ('01) found two abnormal specimens of *Chelopus insculptus* (Le C.) on the basis of which he published a paper on correlated abnormalities in the scutes and the bony plates.

It seemed, then, that this phenomenon needed further investigation and the collection of large numbers of abnormal specimens was begun in the hope of reaching a rational explanation of this very prevalent diversity. Careful study has convinced me that these abnormalities are to be considered not as meaningless anomalies but as examples of systematic atavism in the sense of deVries. From this standpoint it seems possible to throw some light on the phylogeny of *Chelonia*.

The color patterns are intimately associated with the scutes and throw much light on their phylogeny. Consequently a brief consideration of chelonian coloration has been appended.

2. Nomenclature. *The Normal Plate and Scute Pattern.*

The following description and appended drawings (Plate I., Figs. 1 and 2), although referring particularly to an adult female specimen of *Graptemys geographica*, will apply to any genus of the Emydidae. Fig. 1 represents the dorsal and Fig. 2 the ventral aspect.

The armor of tortoises consists of two elements, bony plates and horny scutes, which for brevity will be referred to as *plates* and *scutes*. Dotted outlines are used for the plates and solid outlines for the scutes. In labeling, small letters are used for plates and capital letters for scutes.

A. Plates. — There are in the *carapace* (Fig. 1) five longitudinal

rows of plates, a single median and two paired rows. The median row has been variously designated as dorsal, vertebral and neural. In this paper the term *neural* will be invariably used. The neural row consists of the following elements: an anterior plate of large size called the nuchal (*nu.*), eight neurals (*n.* 1-8), two procaudals (*pr.* 1 and 2), and posteriorly the pygal (*p.*).

Lateral to the median row are the paired costals (*c.* 1-8), directly overlying the eight pairs of ribs.

Bordering the carapace on both sides and extending from nuchal to pygal are the marginals (*m.* 1-11).

The plates of the *plastron* (Fig. 2) are nine in number — the paired epi- (*e.*), hyo- (*ho.*), hypo- (*hp.*), and xiphi- (*x.*) plastrals, and the unpaired endo-plastral (*en.*).

The hyo- and hypoplastrals articulate directly with the fourth, fifth and sixth marginals and form the so-called "bridge" between the dorsal and ventral armor.

B. Scutes. — On the *carapace* (Fig. 1) there are, as in the case of the plates, five longitudinal rows of scutes that receive the same names as the plates. The median row, *neurals*, consists of a small anterior element, the nuchal (*NU.*), and five large *neurals* (*N.* 1-5). There are four pairs of large *costals* (*C.* 1-4). Twelve pairs of *marginals* (*M.* 1-12) completely surround the carapace with the exception of the small space occupied by the nuchal.

The scutes of the *plastron* (Fig. 2) are twelve in number, consisting of six pairs of large flat elements named from anterior to posterior end as follows: gulars (*G.*), humerals (*H.*), pectorals (*P.*), abdominals (*A.*), femorals (*F.*), and anals (*AN.*).

At the angles made by the junction of the pectorals and abdominals with the marginals are two pairs of small triangular scutes called respectively axillaries (*X.*) and inguinals (*I.*). These constitute all that remains in the Emydidae of the *inframarginals*, a row much more prominent and complete in more primitive families.

No other plates or scutes occur normally among the Emydidae, but for the sake of completing the nomenclature, it should be mentioned that one species, *Macrochelys temminckii*, possesses an additional pair of rows of scutes between costals and marginals,

called *supramarginals*. Traces of a median ventral row of scutes are found normally in some species — and I have given the name "*interplastral*" to this row. A single median scute occurs normally in the anterior part of the plastron of certain specialized groups and receives the name *intergular*.

II. DISCUSSIONS OF THE PRESENT STATUS OF THE QUESTION CONCERNING THE MORPHOLOGY OF THE CHELONIAN ARMOR.

The frequent abnormal occurrence of traces of the inframarginals and interplastrals in *Graptemys geographica*, *Chrysemys marginata* and *Chelydra serpentina* led me to review the literature relating to the evolutionary history of the chelonian carapace and plastron.

For nearly a century the chelonian armor has offered to morphologists a problem of unusual difficulty, and, although much has been written on the subject, its derivation is still unsettled. The question has been attacked from the three standpoints of paleontology, embryology and comparative anatomy.

1. *Paleontological* data are far from conclusive. It is not possible to go into this phase of the subject at all fully. Baur in 1887 published a brief summary of the more valuable paleontological data in an article entitled "On the Morphogeny of the Carapace of the Testudinata." A brief statement of the substance of this paper will, perhaps, serve to show the inadequacy of the paleontological evidence in this case.

The condition seen in the *Dermochelydæ* is considered to be the most primitive. Fossil remains of this group agree closely with the existing *Dermochelys coriacea* in the possession of "a pavement of small osseous plates extending over the whole shield, jointed to one another by more or less fine sutures. The number of these plates is much larger than that of the other Testudinata, which is never more than 70." This pavement of osseous plates is not united with the internal skeleton, as are the plates of other Testudinata, but has an independent dermal origin. "That the carapace of the *Dermochelydæ* is homologous to the carapace, without internal skeleton, of the rest of the Testudinata, there is no doubt." The fusion of the dermal pavement bones with the ribs and vertebræ is, according to Baur, proved by a

specimen of *Eretmochelys imbricata*, a fossil species in which are found "small polygonal plates of the same shape as those of Dermochelys, suturally connected with the third, fourth, fifth and sixth costal plates." "A form between the Dermochelydæ and "*Thecophora*" (Dollo) is represented by the oldest known turtle, *Psephoderma alpinum*, H. v. Meyer, from the Triassic of the Bavarian mountains, preserved in Munich. In this highly interesting specimen, never mentioned in monographs on the Testudinata, we have certainly not less than 193 plates suturally united." According to Zittel's Paleontologie, Baur later expressed the opinion that *Psephoderma* may not be a chelonian at all, but perhaps a nothosaurus. Thus doubt is cast upon the best link in the chain of evidence. That all the principal groups of *Chelonia* were in existence in the earlier Mesozoic ages and that Palæozoic *Chelonia* are entirely unknown are familiar facts. So our attempts to reconstruct an ancestral condition must be made largely on the basis of embryology and comparative anatomy.

2. Nor is *embryological* evidence of chelonian phylogeny at all conclusive. The best and most recent study of the developmental history of the chelonian carapace and plastron was made by Goette in 1899. He summarizes the previous literature on the subject and shows that the main question at issue is that of the character of the neural and costal plates. Some authors, principally paleontologists, have maintained that these structures have a dermal origin and hence arise independently of the internal skeleton. Others hold that these plates are mere outgrowths of the ribs and spinal processes of the vertebræ. Goette favors the latter view and presents as evidence of its correctness a series of very careful embryological studies.

Suspecting that there might be some flaw in Goette's work, I repeated much of it, using the embryos of *Chelydra serpentina* and *Graptemys geographica*, and have satisfied myself that the neural and costal plates actually do originate as outgrowths of a differentiated tissue that surrounds the neural and rib cartilages. Whether this differentiated tissue be true periosteum, as Goette affirms, or simply a somewhat denser portion of the connective tissue that fills the space between the epidermis and the cartilagi-

nous skeleton, is not certain. Haycraft ('99) maintains the latter view, but his paper is far from convincing.

As to the remaining plates of the carapace—nuchal, procaudals, pygal and marginals—there is no difference of opinion. All agree that they are of true dermal origin.

Thus it would seem that the plates of the carapace have a dual origin—the neurals and costals being periosteal ossifications while the nuchal, procaudals, pygal and marginals are dermal ossifications.

The carapace, then, as it exists to-day is not a simple structure but consists of a complex of at least two independent systems of bones.

Accepting the evidence of embryology as to the origin of the neural and costal plates, it remains to determine whether the dermal ossifications are, as Goette believes, mere supplementary structures that have come in to supply the deficiencies of the periosteal system, or are remnants of a once more or less complete dermal carapace that has in large measure been rendered superfluous by the broadening-out of the ribs and neural processes. The latter view would involve the former existence of complete rows of dermal bones overlying the vertebræ and ribs. Embryological evidence seems contrary to this view, as no dermal ossifications are found in the costal or mid-neural regions. It is possible that we may in this case overestimate the evidence of embryology as a guide to phylogeny. The great antiquity of the chelonian carapace is undoubted and in highly specialized structures that have attained a marked morphological fixity we should not be surprised to find great condensation in development, so that two structures formerly independent in origin—such as dermal and periosteal plates—may originate simultaneously so as to form only one inseparable structure. It seems quite plausible, then, that the rapid secondary broadening of ribs and neural processes has crowded out or appropriated the primordia that formerly went to form the dermal carapace and that only in places where the ribs and neural processes fail to reach the dermis do the true dermal bones have a chance to appear.

The fact that the nuchal plate appears before the ribs and

neural spines have even commenced to broaden out and that the procaudals and the marginals follow before the neurals and costals are completely organized, points to the antiquity of these dermal structures and indicates that the neurals and costals are of more recent origin.

3. *Comparative anatomy* furnishes us much valuable evidence. In the family Trionychidae, for example, we have a series of forms that show a gradual reduction of a portion of the dermal armor. Fossil Trionychidæ are well known in which are shown a nuchal, a procaudal and a nearly complete set of marginal plates. Such a form was figured by Dollo in 1884 and named by him *Pseudotrionyx*. Another fossil species discovered by the same palæontologist and named by him *Emyda granosa*, lacks the procaudal and the marginals from the anterior half of the carapace. A third form, *Emyda Ceylonensis*, possesses a nuchal and several marginals at the posterior part of the carapace. The extreme limit of reduction is seen in *Aspidonectes spinifer*, which possesses only the nuchal plate as the last remnant of the dermal carapace.

It will be noted that the order of the appearance of these dermal ossifications in ontogeny is just the inverse of the order of disappearance in phylogeny. The latest elements to be formed in ontogeny are the first to disappear in phylogeny. This is just what we would expect if we consider that there has been a gradual shortening of the developmental process, a gradual elimination of the latest stages. The Trionychidæ show clearly that there is a marked tendency to reduce the system of dermal bones and it is not difficult to imagine that earlier reduction has taken place in which the dermal ossifications of midneural and costal regions were lost.

What evidence have we that such dermal ossifications overlying neural processes and ribs actually existed? O. P. Hay ('97) in an important paper dealing with the evolution of the chelonian carapace and plastron, describes and pictures an incomplete carapace of a fossil form named *Toxochelys serrifer*. Three ossicles occur above and overlapping the neural plates and occupy positions coincident with the keels of the second, third and fourth neural scutes. These ossicles have the general form

of the tubercles seen on the dorsal ridge of the tail of *Chelydra serpentina*, and this suggests that the ossicles of *Toxochelys* are merely a continuation forward of a series of tubercles that must have been present on the tail.

Hay suggests that the keels seen especially in the young of modern *Chelonia* are the representatives of ancient dermal tubercles that formed the chief armor of ancestral forms. That in most cases these dermal ossicles have ceased to form independently of the deeper and more vigorous bony layers is perhaps to be expected as the result of condensation in developmental processes.

The degree to which modern species exhibit keels is extremely varied. Some highly specialized forms show none, or at most one, even in very young specimens, while one very primitive species, *Macrochelys temminckii*, possesses seven distinct keels on the carapace and four rows of flat scutes on the plastron. This multiplicity of keels is evidently a very primitive condition and naturally suggests to Hay the condition seen in *Dermochelys coriacea* in which twelve well-marked keels are found, each keel consisting of rows of dermal ossifications that are larger and more prominent than the remaining intermediate ossicles that form the continuous pavement of the test. This peculiar aberrant chelonian is taken by Hay, following Baur and others, as the hypothetical ancestral type from which our modern chelonians have been derived by a process of simplification.

A survey of the field reveals the fact that the nearest approach to this condition of twelve rows of keels is seen in *Macrochelys temminckii*, which possesses seven distinct keels on the carapace. The four rows of flat scutes on the plastron may once have been keeled, for keels on the plastron are known in both extinct and living groups. The total number of keels or keel equivalents in *Macrochelys* is then eleven, one short of the supposed ancestral condition. The missing keel is the mid-ventral one and is represented in certain groups by intergulars. Thus all of the ancestral keels find representatives among modern species.

Hay seems to have been the first observer to suggest the importance of the scutes as factors in the evolution of the carapace. Previous authors have confined their attention to the bony struc-

tures, considering the scutes as of little significance. Hay's view of the rôle of the scutes may be stated briefly as follows: The probable ancestral condition is that seen in *Dermachelys*, the skin of which is found to be broken up into small polygonal areas, larger in the keels than elsewhere. These areas coincided with the osteodermal plates that are or will be developed in the skin. As the deeper elements of the carapace (neural and costal plates) increased in protective efficiency, the dermal structures were in many regions rendered superfluous and disappeared. In some cases the scutes were lost with their corresponding plates, in others the lost plate left its trace in the keel of the scute. The direction of growth of each of the existing series of scutes shows the direction of encroachment on other rows now lost.

This exposition of Hay's seems to me to be the most rational yet advanced, yet I believe that he fails to appreciate the evidence of embryology and thus introduces undue complexity. In the first place, he considers the nuchal plate as a fascia bone instead of an ordinary dermal plate. In the second place he states that the neural and costal plates are of the same character as the nuchal. Embryology shows that the nuchal plate is as true a dermal bone as are the marginals, while the neurals and costals are true periosteal expansions. It seems to me more rational to suppose that the dermal ossifications of the mid-neural and costal regions have undergone a complete suppression identical with that indicated by the series of *Trionychidæ* described above, rather than that they have become indistinguishable by fusion with the rib and neural fascia bones, as Hay calls them.

If we remove the scutes and underlying dermis from the carapace of a specimen of *Chelydra* we find that the long tubercles on the neural and costal plates bear no constant relation to the plates themselves, but are nevertheless clearly of a piece with them. It was natural for Hay to suppose that these bony tubercles were produced separately and then fused with the underlying plates. I have been able to trace this matter to a conclusion in the young of *Chelydra*, with the result that I have seen all the stages of ossification in the carapace and know that the tubercular keels on the neural and costal plates are produced by gradual thickenings of the growing plates. These thickenings

send out branching processes that gradually displace the dermal connective tissue of the tubercles and fill the space with bone. Complete ossification of these tubercles does not occur until the animals are several years of age.

III. DESCRIPTION AND DISCUSSION OF ABNORMALITIES.

That a process of reduction both in the number of rows of scutes and in the number of scutes in surviving rows has taken place seems highly probable. From this standpoint I made a systematic study of all the abnormal specimens that showed traces of these lost rows or lost scutes. Inframarginals of all grades of prominence were found in specimens of *Graptemys geographica* and *Chrysemys marginata*, while interplastrals were found more rarely in the same two species. It will be noted that both of these recurring rows are plastron rows which probably means that the carapace has reached a high degree of fixity with reference to number of rows. Yet many abnormalities are found that indicate that the reduction in the number of scutes in a row was of comparatively recent occurrence.

These abnormalities will be discussed under three heads: (1) Inframarginals, (2) interplastrals, (3) supernumerary scutes in a row.

1. *Inframarginals.*

The occurrence or non-occurrence of inframarginals has formed the basis for separating the Thecophora into two great groups. Gadow in his volume on Amphibia and Reptiles gives Boulanger's key for classifying *Chelonia*. In this the two groups are characterized as follows:

1. Pectoral shields separated from the marginals by inframarginals — Chelydridæ, Platysternidæ, Cinosternidæ.
2. Pectoral shields in contact with the marginals — Testudinidæ, Chelydidæ, Pelomedusidæ.

It is evident that the more primitive families possess as normal factors this row of scutes while the more specialized families *normally* lack this row. When, however, dozens of specimens of *Graptemys* and *Chrysemys* possess this row in more or less perfect form, I am forced to consider this phenomenon as a well-marked case of systematic atavism. In view of the fact that no

such anomalies have been previously described, it seems worth while to tabulate those in my collection — an easy task in view of the fact that the scutes occur in definite places. In any species, such as *Chelydra*, that possesses this row normally, there are typically three scutes in the row, one in contact with the axillary, one at the angle of contact of the pectoral and humeral and the marginals, and one abutting on the inguinal scute. These three scutes may be designated respectively as I., II. and III. Out of 476 specimens of *Graptemys geographica* examined, I found 31 with traces of inframarginals varying all the way from three large scutes on each side to one small one on one side. The tabulation below gives the number of the specimen, the sex, the length and breadth of carapace in millimeters, the occurrences of inframarginals on the right and left sides separately. Three general sizes are distinguished, which although quite arbitrarily laid down may serve to give a more definite idea of the amount of variation that occurs. These sizes are designated as large, medium and small.

At Woods Hole this summer I found two specimens of *Nanemys guttata* and three specimens of *Chrysemys picta* with well marked inframarginals.

It will be readily seen that in both species the middle scute is much the commonest recurrence, and this is natural if we consider that in *Chelydra*, and other species with well developed inframarginal rows, the middle scute is always the largest. The largest and most vigorous scute would probably persist longer and hence be most likely to recur as an atavistic reminiscence. The fact that no. III. is next in prevalence in *Graptemys* and no. I. in *Chrysemys*, indicates that the order of suppression of the other scutes of the row was subject to individual and group variation.

In the species *Chelydra serpentina* the inframarginal row is in a highly variable condition. Many stages in the reduction of numbers of scutes are to be seen in different individuals. The middle scute, corresponding to no. II., is always the largest, and the adjoining ones are next in size and would correspond to no. I. and no. III. Frequently there are two or three smaller scutes both in front of and behind the large central scutes, but

they shown signs of suppression and in the majority of specimens are of insignificant size. The axillary and inguinal scutes of the Emydidae, etc., correspond, I believe, to two of these smaller scutes that are undergoing suppression in *Chelydra*. They have persisted in the Emydidae probably because they were needed to fill in the angles between the plastrals and marginals. *Aroma-*

CHRYSEMYS MARGINATA (188 specimens examined).

I.	4 scutes		2 scutes
II.	8 "		4 "
III.	1 "		1 "
Total :	13 "		7 "

chelys odorata (Fig. 53) shows a curious survival of inframarginals, having invariably only two scutes, one large and the other very small and vestigial. From its position, separating the pectoral shields from the marginals, I would homologize this large scute with no. II. and the vestigial scute with no. I. Complete suppression of the inframarginal row has occurred in the terrestrial genera of the Emydidæ.

2. Interplastrals.

The occurrence of traces of the interplastral row are not nearly so frequently found as those of the inframarginals. Yet they are sufficiently numerous and definite to note in this connection. Traces have been found in *Chelydra*, *Graptemys* and *Chrysemys*. In preparing a list of these occurrences it will be convenient to number the places where such scutes might occur,

A, *B*, *C*, *D* and *E*, beginning at the anterior end. Two specimens of *Chrysemys marginata* have extra scutes at *A* (Fig. 47). Two specimens of *Chelydra* have extra scutes at *C* (Fig. 45). One specimen of *Graptemys* has extra scute at *D* (Fig. 48). One specimen of *Graptemys* has a pair of extra scutes at *E* (Fig. 46). The primitive condition was probably one in which a scute was present at each point of union of four plastron scutes, but the fact that even in the tail of *Chelydra* this row is either partially or wholly wanting indicates the rather uncertain character of the row. In the specimens listed above scutes are found occurring in four places out of a possible five. No doubt a larger collection would serve to fill in this gap.

I consider these recurrences as true reversions to ancestral conditions; and that they come under the head of systematic atavism I see no reason to doubt.

How the typical number of scute rows seen in our modern tortoises has been acquired has, perhaps, been sufficiently discussed and it now seems necessary to consider the processes that have brought about the reduction of the number of scutes in a row—for it is beyond dispute that such a reduction has taken place.

3. *Supernumerary Scutes in a Row on the Carapace.*

The literature on this subject is limited to one paper, Gadow's much-discussed "Orthogenetic Variation in the Scutes of Chelonia," that was published in Willey's Zoölogical Results in 1899. The author gives a very interesting account of the conditions found in the common loggerhead turtle, *Thalassochelys caretta*. He has gathered together a miscellaneous assortment of some sixty-nine specimens of various sizes, principally new-born, from many parts of the world. On the basis of this collection he comes to the conclusion that scute reduction proceeds along certain definite lines. His observations, however, are limited to reductions in the neural and costal rows. According to Gadow, the ideal ancestral condition is one in which the neural and costal bony plates determine the number of scutes. The author's idea is that there was originally a scute for each of these plates.

Starting with this ideal condition as stage I., he finds the nearest approach to it in specimen 1, that has 8 left costals of which 2 are vestigial, 8 right costals of which 1 is vestigial, and 8 neurals. The greatest reduction is that seen in specimen 26, which has 5 left costals of which 1 is vestigial, 4 right costals, and 7 neurals of which 1 is vestigial. This latter specimen is reduced below the normal for the species, which is arbitrarily said to possess 6 neurals and 5 pairs of costals. This condition is said to be the goal toward which every young *Thalassochelys caretta* is striving.

The following stages are mapped out in diagram, following Gadow, to show the sequence in scute reduction in the chelonian carapace :

Stage I. — Hypothetical, eight neurals and eight pairs of costals. Neurals and costals lie in the same transverse plane and coincide with neurals and costal plates.

Stage II. — Eight neurals and eight pairs of costals, the latter fitting with their inner angles dovetailed between two successive neurals. Rearrangement probably brought about by the partial reduction of one pair of costal scutes. This reduced pair is probably the second.

Stage III. — Eight neurals and seven pairs of costals, the original second costals suppressed, original third becoming second, etc.

Stage IV. — Seven neurals and seven pairs of costals, but fifth neural and fourth pair of costals (original fifth), in a state of reduction.

Stage V. — Six neurals and six pairs of costals, owing to complete suppression of fifth neural and fourth (original fifth) pair of costals.

Stage VI. — Six neurals and five pairs of costals, brought about by fusion of last two pairs of costals into one or, perhaps, by suppression of one pair. This is the normal condition in *Thalassochelys*.

Stage VII. — Six neurals and four pairs of costals. Normal condition in the majority of tortoises to-day, brought about by suppression of first pair of costals.

Stage VIII. — Six neurals and four pairs of costals, first neural (nuchal) greatly reduced.

Stage IX.— Five neurals and four pairs of costals, first neural (nuchal) suppressed as seen in pleuroderous tortoises.

Beyond this last stage chelonians have not ventured yet, at least normally.

The order of loss in scutes is according to Gadow: (1) No. 2 costals, (2) no. 7 neural, (3) no. 5 neural and no. 4 (original no. 5) costals, (4) no. 7 or 8 costals (by fusion or suppression), (5) no. 1 costals, (6) no. 1 neural.

Gadow's paper, while most suggestive, must be criticised in several particulars, but before proceeding to the criticism it will be necessary for me to produce the data that to a large extent form the basis of the criticism. The data are derived from a collection of a large number of abnormal specimens, principally of two species, *Graptemys geographica* and *Chrysemys marginata*. Gadow worked on a species that is normally abnormal — if such an expression be permissible. He selected the commonest condition and arbitrarily called it normal. As a matter of fact, there is no normal or fixed condition. The species *Thalassochelys caretta* is evidently in a highly variable state as to scute number and arrangement, and no stability has as yet been attained. The species I have studied have, on the contrary, reached an advanced state of stability. Yet a sufficiently large number of abnormalities occur to give one nearly as many examples as Gadow had. Out of 476 specimens of *Graptemys*, varying from embryos to adults and taken at random, there occurred 48 specimens with supernumerary carapace scutes, while 188 *Chrysemys* yielded 8 such abnormal specimens. Four other species belonging to widely diverse groups yielded one abnormality apiece. It seems probable that abnormalities of exactly the kind that I have found so plentifully in the case of *Graptemys* and *Chrysemys* are to be found in any species if enough specimens be examined.

In order to economize space in the tabulation of these abnormalities brevity in the nomenclature of these vestigial scutes must be attained by numbering them. Combining Gadow's figures with my own results, I have good reason to believe that vestigial scutes occur between every two surviving normal scutes and that the first, second and last costals are also found in a vestigial condition. On this basis, then, there were eleven neurals and ten

pairs of costals. These, if numbered from anterior to posterior, would give the numbers 1, 3, 5, 7, 9 and 11, to surviving neurals, and numbers 2, 4, 6, 8 and 10 to vestigial or lost neurals; the numbers 3, 5, 7 and 9 to surviving costals, and numbers 1, 2, 4, 6, 8 and 10 to vestigial or lost costals. In the tabulation these numbers will be used without further explanation. Furthermore, the sex, length and breadth of carapace, brief descriptions of both scutes and bony plates, will be given in separate columns. The significance of the tabulation of conditions of bony plates will be seen later when the subject of correlation between scute and plate abnormalities is discussed. The specimens are numbered and arranged in the order of abnormality, the specimens with largest number of extra scutes coming first, and those with less than the normal number of scutes last. Extra neurals will be listed before extra costals and the latter before extra marginals.

Two kinds of abnormality may be distinguished: symmetrical and asymmetrical. The former are less common and are important in that they furnish clearer cases and thus throw light on the latter. Under the head of symmetrical abnormalities may be mentioned extra neurals in the median line or nearly so; extra costals in pairs symmetrically placed; extra paired marginals. The great majority of abnormalities are asymmetrical, consisting of: extra neurals crowded to one side or the other but usually showing clearly enough the position they would normally occupy; unpaired costals or marginals. In the case of asymmetrical neurals it is sometimes difficult to distinguish the supernumerary scute from the normal scute, on account of the large size of the former and the fact that crowding has forced the two scutes to lie approximately side by side. There are usually correlated points of asymmetry that may be of assistance in deciding the point, but occasionally I have been compelled to trust to my judgment and may possibly have erred. Gadow would probably consider the type in which the normal and supernumerary scutes lie side by side as evidence of the original paired character of the neural row. Were it not for transitional conditions this view might be tenable.

Occasionally it becomes difficult to determine which of five costals is the supernumerary scute, but a reference to the mar-

ginals will usually settle the point, as the normal condition has a very characteristic arrangement of these two sets of elements.

Another source of difficulty arises from the complete or incomplete fusion of adjacent scutes. Fusion is due to the inhibition of the process of division into epidermal areas at a rather late embryonic stage. In some cases the fused scutes show their separate identity, after a year or two of growth, by a separation of their growth rings. Coker has called attention to several such cases in connection with *Malaclemmys centrata* and I have observed the same phenomenon in the marginals of *Graptemys* on several occasions. Usually, however, the indications are clear enough to enable one to recognize the individual elements in a fused scute. It seems reasonable in the present discussion to consider the number of scute primordia involved in a fusion and to give them the full rank of independent scutes.

As in the previous tabulation, the arbitrary terms, large, small and medium, are used. L or R in connection with neurals will

indicate that the extra scute is crowded to left or right. The same letters indicate the side on which extra costals and marginals occur.

The following isolated abnormalities have come to hand and may be listed :

Large specimen of *Terrapene carolina* has a R 10 costal (medium).

Medium-sized shell of *Cyclemys dentata* has paired 6 costals (medium). See Fig. 42.

Two medium-sized specimens of *Chelydra serpentina* have L 10 costal (large).

Large *Aromochelys odorata* has R 10 costal (medium).

A reference to the literature enables me to list a considerable number of similar abnormalities. The names used in the references will be retained.

1. *Ptychemys elegans*, Agassiz, L., Contributions to the Natural History of the U. S., Plate I, Fig. 13, showing : L 4 neural, paired 4 costals, paired extra marginals. (Figured in this paper as Fig. 33.)

2. *Chelopas insculptus*, Parker, G. H., paired marginals lacking.

3. Same : R 8 and 10 neurals, R 10 costal, R marginals lacking.

9. *Testudo areolata* (Thunberg), Tab. XXIII., median 8 neural, L 6 costal.

10. *Testudo planiceps*, XXVII., L 4 costal.

Discussion.

A scute, whether normal or supernumerary, is a separate and definite entity, resulting from a definite embryonic primordium.

The fact that supernumerary scutes have been found between all of the normal scutes as well as at both ends of the costal series must have some significance. If one assumes that these supernumerary scutes represent the atavistic recurrence of scutes that have been lost in the course of phylogeny, it is possible that the following tabulation will throw some light on the sequence of loss.

<i>Neurals.</i>		<i>Costals.</i>	
No. of Scute.	Numbers of Recurrences.	No. of Scute.	Numbers of Recurrences.
2	1	1	6
4	2 (one doubtful)	2	0
6	5 (one doubtful)	4	3
8	11 (one doubtful)	6	4 (one doubtful)
10	16 (one doubtful)	8	4 (one doubtful)
		10	35

It will be seen that the most frequent recurrences are at the posterior end of the carapace, and that, with the exception of the first costal, the frequency of recurrence diminishes as we proceed anteriorly. What significance attaches to this fact? It seems quite probable that the most frequent recurrences represent the most recent losses and the rarest recurrences the most ancient losses. This rule held good for the suppression of rows of scutes and should apply here also.

On this basis then we can at least say that the succession of suppression was in general antero-posterior, that the earliest losses occurred at the anterior end of the carapace and the most recent losses at the posterior end. One might go further and say that in the neural series the order of suppression was probably 2, 4, 6, 8 and 10. The antero-posterior order of loss is not so clear in the case of the costals, as no. 1 costal recurs more frequently than any other except no. 10. This means a modification of the regular mode of progression. In the costal series it is probable that the antero-posterior succession of losses was interfered with by the rounding-in of the marginals both anteriorly and posteriorly. This rounding-in would necessarily begin about medially and proceed in two directions, hence the second supernumerary scute would be put under pressure before the first and the eighth before the tenth. The antero-posterior

tendency, however, would bring about the suppression of anterior scutes, as a whole, before posterior scutes.

Evidences are not wanting that scutes may be suppressed and the method of suppression seems clear. In a specimen of *Cyclemys dentata*, listed as no. 58 and figured on Plate III., Fig. 42, the paired sixth costals are being encroached upon by the seventh costals. The anterior growing margins of the latter have pushed in under the posterior edges of the former in such a way as to severely cut into their growth centers. The dotted line shows the amount of encroachment. Several specimens of *Graptemys* show the same phenomena, and the scutes encroached upon are always the supernumerary ones. This may be looked upon as a recurrence of an ancestral condition and we may infer that the loss of certain scutes has been brought about through the encroachment, more and more severe with succeeding generations, of more vigorous upon less vigorous scutes, resulting in the final complete suppression of the latter. We must also suppose that the rudiments of the lost scutes lie dormant in the embryonic tissues and occasionally for some reason reappear more or less completely. Those that have been suppressed for the longest time would naturally reappear least often and *vice versa*. On this basis, then, we may safely say that the order of loss is orthogenetic if by this we simply mean onward development.

Applying the same methods to Gadow's figures I find a very general agreement, although I am unable to agree with the author's interpretations. The vestigial scutes that occur in Gadow's figures are : neurals 2, 8 and 10 ; costals 1, 2, 4, 6, 8 and 10. No. 2 costal was not found in my specimens, but is so clearly seen in Gadow's Fig. 1 that I have introduced it into my system. It is possible that No. 2 costal was the most ancient loss and hardly likely to recur in specialized types such as *Graptemys* and *Chrysemys*, since it occurred only once in Gadow's specimens of *Thalassochelys*. It will be seen that Gadow finds no vestiges of neurals 4 and 6. An examination of his figures will show that *Thalassochelys* has attained a high degree of fixity in the anterior portions of the mid-neural series, while all other regions are still in a decidedly variable condition. Hence we are

unlikely to find vestigial scutes in this region unless a much larger number of specimens is examined.

Carapace abnormalities have been pictured by authors for over a century and I have on my lists fourteen species, belonging to widely diverse groups, that show the same general abnormalities.

These scattering cases could scarcely be used in determining the order of loss of scutes, but are of importance in that they show that certain abnormalities that are comparatively rare in *Graptemys* and *Chrysemys* occur with a fair degree of frequency in other forms. For example: neurals 4 and 6, and costals 1, 4 and 6 occur from 2 to 4 times in these specimens. The prevalence of abnormalities of this sort over such a wide range of forms strengthens my idea of the universality of the process of scute reduction in *Chelonia*. I have no doubt that such abnormalities will be found in any species if enough forms are examined.

In Gadow's diagrams illustrating the progressive reduction of epidermal scutes (p. 217) it will be seen that the order of reduction differs from the one I have proposed in two points; in the first place he indicates that no. 10 neural is suppressed before no. 8, but this is not borne out by his own figures. Figs. 4, 6, 7, 14, 20, 26, show no. 10 persisting after the total suppression of no. 8, Fig. 26 being especially convincing. Figs. 8, 9, 10, on the other hand, show no. 8 persisting after the suppression of no. 10. The balance is decidedly in favor of the earlier suppression of no. 8, yet there must have been some individual variation in this matter. My own figures show that no. 8 recurs twelve times as compared with seventeen times for no. 10. In my own specimens there are eight cases in which nos. 8 and 10 neurals recur together, nine cases of no. 10 recurring alone, and only four of no. 8 recurring alone. It would seem then that these two scutes were undergoing a process of suppression at about the same time, but that no. 8 was in most cases the first to disappear.

In the second place it seems clear that no. 1 costal persisted longer than no. 10 in *Thalassochelys*, but that the opposite was the case in all the forms in my collection can scarcely be doubted. no. 10 recurs thirty-six times and in many species, while no. 1 recurs only six times.

Some rather remarkable conclusions are expressed in Gadow's paper and should be discussed in this place.

1. He makes the following statement: "Abnormalities are 4 to 7 times as common in new-born as in mature specimens, hence scute reduction must take place during the lifetime of the individual." I have not had the opportunity of putting this matter to a test in the case of *Thalassochelys*, but the examination of several complete nests of *Graptemys* has brought to light the following facts. Two nests containing respectively thirteen and fourteen embryos showed no abnormalities. One nest containing fourteen just-hatched young showed one slight abnormality, a vestigial no. 10 costal. A fourth nest in which twelve eggs came to maturity contained five decidedly abnormal specimens, listed as nos. 11, 19, 25, 26 and 48. This means that barely 10 per cent. of the embryos of four broods are abnormal, while out of 476 specimens of *Graptemys* 48 were abnormal in the carapace scutes, a little over 10 per cent. A large proportion of Gadow's new-born specimens came from one nest, the whole brood of which was abnormal. The others were taken in small sets from various collections, and I believe that such specimens had been preserved because of their abnormalities. A survey of my tabulations will show that abnormalities are no more common in one size than in another. Finally, Coker, in a very recent preliminary paper, delivered before the American Society of Zoologists in Philadelphia, December, 1904, claims that observations on embryos of *Thalassochelys* gave no support to the theory of Gadow.

2. Gadow considers that certain specimens (Figs. 6 and 24) show evidences that the neural row was originally a double one. That this was the case seems very unlikely from an examination of such primitive conditions as are seen in the tail of *Chelydra* and in the neural keel of *Dermochelys*. The appearances seen in Figs. 6 and 24 may be due to the crowding of linear members of the row until they come to lie side by side. Indications of an approximation to this condition are not uncommon in the specimens which I have had to deal with.

4. *Supernumerary Scutes on the Plastron.*

The *plastron* has, as a rule, reached a higher degree of fixity in the matter of numbers and arrangement of scutes than has the carapace, but that this portion of the chelonian armor has not always had so fixed a character may be seen in the high state of variability of *Aromochelys odorata*, which is almost as marked as that seen on the carapace of *Thalassochelys*. In *Aromochelys* the number of plastron scutes varies from 14 to 9 and all intermediate conditions are readily found. Fig. 52 shows the largest number of scutes seen in the specimens of my collection. In this case there is a well-developed extra pair of scutes between the abdominals and femorals. Fig. 53 shows the commonest condition in which there are the usual five pairs of plates and the gulars are partially fused. Fig. 54 shows the extreme of reduction in which the pectorals have been lost either through crowding or fusion, and the gulars have fused into a single median element.

As in the case of the carapace, we find in several species that have attained a high degree of fixity in the plastron, marked traces of supernumerary scutes. Fig. 49 shows the plastron of a small specimen of *Chelydra* that has an extra pair of scutes between femorals and anals. Fig. 50 shows another specimen of *Chelydra* with a vestigial scute on the right side between humeral and abdominal. Fig. 51 shows a specimen of *Chrysemys* with a well-marked supernumerary scute on the left side between abdominal and femoral. In Figs. 49, 50, 51 and 52 we have supernumerary scutes in four places out of a possible five. As yet I have been unable to find supernumerary scutes between gulars and humerals.

Losses seem to have taken place in two ways: by fusion and by crowding out. Some curious examples of the latter might be mentioned. In *Chelydra* the abdominals have been forced to the sides, but have been retained to bridge the gap between the small plastron and the margin of the much larger carapace. In other cases the pectorals have played a similar rôle. Van Lidth de Jeude describes a specimen of *Testudo ephippium* (Gthr.), in which the pectorals have been crowded to the two sides like the abdominals of *Chelydra*. Other specimens of the same species, according to Rothschild, have the same abnormality to a greater

or less degree. The Catalogue of Shield Reptiles in the British Museum shows a specimen of *Monouria fusca* (Tab. III.), in which the pectorals are crowded to the margin of the plastron and have become small and triangular. The same volume shows a specimen of *Sternotherus Derbianus* (Tab. XXII.), in which the pectorals seem to have a tendency to be suppressed or crowded to one side.

On the whole it seems evident that an orderly suppression of alternate scutes has taken place in the plastron as well as in the carapace.

5. *Correlated Abnormalities in the Scutes and Bony Plates.*

The next question that comes up for discussion is whether or not there is any correlation between scutes and bony plates. It has long been noticed by morphologists that there is a certain definiteness about the relative positions and sizes of scutes and plates. This may be described in brief as a definite overlapping of bony sutures by scutes. In the marginal series (see Fig. 1) this is seen in its simplest form — every bony suture being covered by a scute. In the neural and costal series one scute as a rule covers one whole plate and half of two adjoining plates. This arrangement is modified in the anterior and posterior regions. In the former the nuchal plate is partially overlapped by six scutes, viz. : nuchal, first pair of marginals, first pair of costals (normally involving only small corners of the plate), and the first neural. The first costal scutes cover the first and half of the second costal plates as well as the inner edges of first, second, third and fourth marginal plates. The last neural covers normally parts of eight plates, viz. : the two procaudals and the anterior margin of the pygal, about half of the eighth neural and eighth pair of costals, and the anterior margins of the eleventh marginals. Only in the middle portions of the carapace is any definiteness of arrangement seen, yet there is a marked fixity of relations even in the most specialized regions. Gadow bases his reduction series upon an arbitrary connection between these structures, according to which there was originally a scute for each vertebra and rib. He gives no reason for assuming a vital connection between these structures, but simply implies one. In an earlier portion of the

present paper it has been shown that there is no ontogenetic connection between the scutes and plates, the former being laid down before the latter have begun to form, while the latter appear comparatively late in development as mere outgrowths of the ribs and neural spines.

If, however, there be any essential connection between these scutes and plates, we would expect to find scute irregularities and abnormalities associated with plate irregularities and abnormalities and *vice versa*.

G. H. Parker ('99) expresses himself at some length on this point in a paper entitled "Correlated Abnormalities in the Scutes and Bony Plates of the Sculptured Tortoise." He describes in detail two abnormal specimens and on this slender basis reaches some rather general conclusions.

Specimen no. 1 has extra eighth and tenth neurals and a small right tenth costal. No plate abnormalities are found in the neurals or costals, but one right marginal plate and a corresponding scute are lacking. Parker designates these conditions as : (a) Scute abnormalities unassociated with plate abnormalities, (b) scute abnormalities associated with plate abnormalities.

Specimen no. 2 has normal neural and costal scutes, but lacks an entire horizontal row of plates consisting of a neural, a pair of costals and a pair of marginals. The lack of marginal plates is associated with the lack of a corresponding pair of scutes. These conditions are designated as : (a) Plate abnormalities unassociated with scute abnormalities, and (b) scute abnormalities correlated with plate abnormalities. Parker finds the second specimen shorter than the average normal specimen of the same sex in the proportion of 1.298 to 1.313. This is due to the loss of a vertebra and pair of ribs.

In both cases it will be seen that the only real correlation occurs in the marginals and that here the correlation is perfect. Another correlation not mentioned by the author is seen in the second specimen, where there is a reduction of marginals in sympathy with the reduction in neurals and costals. This correlation is, I believe, of a different sort from that seen in the marginal plates and scutes, in that a common cause has brought out the same general effect in both sets of structures. In both cases of

correlation in the marginals Parker concludes that the abnormality is in the anterior portion of the carapace, but an examination of his figures fails to convince me that he has any criterion for thus locating the point of suppression or recurrence of scutes, for a loss anywhere in the marginals would necessitate a general readjustment with reference to the costals. Yet the author concludes that correlated abnormalities are likely to occur only in the anterior portion of the carapace.

To aid this hypothesis he adds a second one, based on a paper by Harrison ('98), in which it is shown that in the frog larva the ectoderm is proliferated chiefly at the anterior end and the mesoderm chiefly at the posterior end. This would cause the ectoderm to slide back over the mesoderm. Parker concludes that the ectodermal structures in the carapace have migrated away from their mesodermal connections so that the posterior scutes are far from their original plates, while in the anterior part of the carapace the scutes are over the same plates that they originally covered.

This ingenious hypothesis loses its force when, after the examination of large numbers of abnormalities, it is found that nearly all true correlations of plates and scutes occur at the posterior end of the carapace.

A reference to the tabulation of abnormalities will bring to light the following facts:

1. Specimens 2, 4, 6, 30, 45, 47, 61 and 62 show very precise correlation of abnormalities in the marginals. All abnormalities in the marginal scutes are correlated with similar abnormalities in the plates.
2. Specimens 5, 6 and 15 have abnormalities of both plates and scutes of the costal series, but in no case are these strictly correlated. In all three specimens the extra costal plates are paired while the extra costal scutes occur on the right side only. These specimens are abnormally long and the undue length may be the common cause of both extra plates and scutes.
3. No. 9 neural plate recurs in the same three specimens (5, 6 and 15) and is associated in each case with one or more extra neural scutes (Nos. 8 or 10). Examination shows that these extra neural plates are irregular structures, are not associated with the neural processes of vertebræ, and hence are to be con-

sidered in the same category as the procaudals. On this account I am strongly of the opinion that they have had a dermal origin like the procaudals.

4. Specimens 5, 6, 9, 13 and 49 have extra procaudal, either single or double, and in each case this plate abnormality is associated with the recurrence of an extra scute in the posterior part of the neural row. The procaudals are certainly of dermal origin and were probably the bony cores of the last neural scutes before the crowding-out process began. Consequently the reappearance of an extra plate and extra scute in this region may with justice be considered as a case of correlation.

5. Specimens 7, 8, 14, 17, 20, 21, 23, 27, 29, 31, 33, 41, 50, 51 and 58 have various kinds of scute abnormalities and perfectly normal plates.

Summarizing, we find that the only invariable correlations are in the marginals which represent scutes with their bony supports (the plates) only slightly separated from one another; that correlations between extra procaudals (also true dermal plates) occur in five cases and no case of plate abnormality in this region is without a scute abnormality; that correlations between an extra neural of small size and irregular shape occur in every case; that extra paired costal plates are associated with asymmetrical extra costal scutes; and that very frequently scute abnormalities appear without any corresponding plate abnormality.

It would appear then that abnormalities are never truly correlated except in regions where dermal plates persist and never in the anterior part of the carapace, because the plates of that region, except the nuchal, have given way to the periosteal plates of the neural and costal series. The nuchal plate still possesses its scute in a reduced condition, so we would not expect to find any abnormality in that region.

Only in the regions of dermal plates do we find any interdependence of plates and scutes, because only here, according to our theory, is there any genetic connection between dermal and epidermal structures.

That we find no true correlations between the plates and scutes of the neural and costal series is just what we would expect from our knowledge of their ontogenetic independence. In the most irregular specimens, having the most grotesque scute displace-

ments and additions in the mid-neural and costal regions, there is not a single case of sympathetic plate abnormality.

Another strong case in favor of the entire independence of these structures is furnished by examples of vertebral distortions. A paper by Wandolleck (1904) entitled "A Hump-Backed Tortoise," describes a specimen of *Testudo Græca* in which the neural and costal plates were in utter confusion, due to lateral curvature of the spine. Yet the number and arrangement of the scutes was perfectly normal. Another case in point is that of a deformed embryo in my possession that has ten ribs on one side and the number of costal scutes is perfectly normal (Fig. 56).

Further evidence for the independence of neural and costal scutes and plates is derived from the fact that certain land tortoises undergo striking modifications of plates in order to form a dome-shaped shell of great strength. The costal plates become, dovetailed one into the other and are decidedly wedge-shaped. This condition is not followed in any respect by the scutes, which retain their typical form and arrangement. A. Bienz ('94) describes this condition in *Dermatemys mawii*, and shows that the form and the arrangement of the plates conform with the most approved architectural principles.

The origin of the bony plates of the plastron has been thoroughly worked out and in each case a plate is to be interpreted as a modification of preëxisting bony structures — clavicle, sternum or abdominal ribs. If such structures as these have been transformed into large, flat, bony plates without any fusion of fascia bones or any outside factors of any sort, why is it necessary to explain the costal and neural plates as other than mere modifications of the preëxisting ribs and neural spines?

6. *Correlation in Scute Abnormalities.*

Two tendencies may be noted in this connection :

1. Scutes of the same horizontal row have a tendency to recur together (see Figs. 3, 5, 6, 7, 8, 9, 10, 12, 13, 14, 20, 31, 33, 35, 40). A 10 neural most frequently is accompanied by a 10 costal, etc.

2. In asymmetrical abnormalities the tendency is for supernumerary neurals, costals and marginals to occur on the same side (see Figs. 3, 5, 7, 8, 9, 10, 12, 13, 14, 31, 35, 40).
